Key Points:

- Mechanical tests with ultrasonic data of heat-treated, dry and saturated limestones
- Results revealed water and temperature dependence at the brittle-ductile transition
- Integrated in a 2D model, results highlight broad impacts for some volcanic basements

Abstract

Volcanic edifices are commonly unstable, with magmatic and non-magmatic fluid circulation, and elevated temperature gradients having influence on the mechanical strength of edifice and basement rocks. We present new mechanical characterisation of the Comiso limestone of the Mount Etna Volcano (Italy) basement to constrain the effects of regional ambient conditions associated with the volcanic system: the effects of pore fluid on rock strength and the effects of distal magmatic heating (~20°C to 600°C) at a range of simulated...
depths (0.2 to 2.0 km). The presence of water promotes ductile behaviour at shallow depths and causes a significant reduction in brittle rock strength compared to dry conditions. Thermal stressing, in which specimens were heated and cooled before mechanical testing at room temperature, has a variable effect for dry and saturated cases. In dry conditions, thermal stressing up to 450°C homogenises the strength of the specimen such that the majority of the specimens exhibit the same peak stress; at 600°C, the brittle failure is promoted at lower differential stress. The presence of water in thermally-stressed specimens promotes ductile behaviour and reduces peak strength. Acoustic emission monitoring suggests that accumulated damage is associated with the heating-cooling sequence, particularly in the 300-450-600°C. Based on conduction modelling, we estimate this temperature range could affect basement rocks up to 300 m away from minor sheet intrusions and much further with larger bodies. Considering the dyke spacing beneath Etna, these conditions may apply to a significant percentage of the basement, promoting ductile behaviour at relatively shallow depths.

Plain Language Summary

Volcanoes can collapse as a result of underground magma, gas and/or water flows, and temperature effects on its basement rock's strength. We did laboratory experiments to further test the strength of surface samples of a limestone present beneath Mount Etna Volcano (Italy). We kept some samples ‘as-collected’ and heated and cooled the others at different temperatures (up to 600°C) prior to their deformation as if some magma bodies had flown in the vicinity of these rocks. We then water saturated a sample of each temperature condition applied and compared their strengths at different simulated depths ranging about 0.2 to 2.0 km (i.e., confinement ranging between 7 and 50 MPa) to the ones of the corresponding samples kept dry. Our results show that water presence lowers the limestone strength compared to dry conditions but also the conditions of pressure at which the failure behaviour transitions between brittle and ductile regimes. For temperature up to 450 °C, the strength of this limestone seems to be independent of the treatment’s temperature with the maximum strength values being higher in dry conditions than in water saturated conditions. The rock fails only in the brittle regime when thermally treated prior deformation at all temperatures, saturation and confinement applied. Considering the dyke spacing beneath Mount Etna, these combinations of water, temperature and pressure conditions may apply to a significant percentage of the basement, promoting weaker and ductile behaviour at relatively shallow depths.
1. Introduction

Volcanic environments are subjected to many processes that can cause weakening of the edifice and of the underlying basement (e.g. McGuire [1996]; De Vries and Borgia [1996]). In particular, magmatic intrusion via dykes and sills or emplacement of larger magma bodies results in damage growth during emplacement (Voight and Elsworth [1997]), changes to the stress state during and following magmatism (Aloisi et al. [2011], Bonaccorso et al. [2010]), and high temperature gradients (Bonaccorso et al. [2010]). Transient temperature variation may lead to the generation of permanent changes to the hosting material, owing to heat-induced mineralogical transitions, hydrothermal alteration, and intrusion-induced fractures. Extreme cases of thermal alteration and weakening can enhance catastrophic flank collapses (e.g. Voight and Elsworth [1997]; Day [1996]; Elsworth and Day [1999]; Reid et al. [2001]; Dieterich, [1988]). Most studies of such effects focus on the volcanic edifice rocks (e.g. Reid et al. [2001]), or on rocks composing the basement (e.g. Elsworth and Voight [1992]; Delaney [1982], Heap et al., [2013]; Bakker et al., [2015]). Basement rocks typically host some type of pore fluid (water, brine, hydrothermal fluids: e.g. Day [1996], Mattia et al. [2015], Dautriat et al. [2011]), and owing to the distribution of intrusions in subvolcanic systems, much of the sub-edifice basement is likely to be subject to lower – but still elevated – temperatures (i.e. <600 °C).

The presence of a sedimentary substratum under Mount Etna is a known control on the edifice stability for many years (e.g. Van Wyk De Vries and Borgia [1996] Mattia et al. [2015]). The Etnean basement is dominated by a mélangé of deformed sandstones, limestones, clays (Appenninic-Maghrebian Chain, Figure 1) and thick carbonate sequences (Hyblean Plateau, African Units; Figure 1) (Branca et al. [2011]; Lentini et al. [2006]), which have been the subject of previous mechanical characterisation (e.g. Mollo et al. [2011], Heap et al. [2013], Wiesmaier et al. [2015], Bakker et al. [2015]). In this study, we select samples from the carbonate units of the Hyblean Plateau and report new results from an experimental investigation that builds on these previous studies. Specifically, we consider the thermal history of subsurface carbonate sequences with new data on fracture damage due to an imposed deformation. Furthermore, we use these data to simulate the thermal damage induced by a dyke intrusion into the country rocks. The chosen range of temperature (150-600 °C) mimics a rock near enough to be subjected to significant temperature transients (not
directly in contact with the dyke), which is the case of a large proportion of material in natural conditions. The key questions we seek to address here are: (1) how is induced thermal damage captured by elastic wave velocity and Acoustic Emission (AE), and (2) what is the influence of this thermal history on the mechanical properties with respect to fluid saturation? To achieve this, we infer the input of thermal crack damage from contemporaneous AE measurements during a pre-test thermal treatment (cycle of heating then cooling) up to a maximum of 600 °C, on the Comiso limestone (Hyblean Plateau). Comiso Limestone (CL) was chosen because i) it was already previously investigated (Bakker et al. [2015]) and ii) it is a very good analogue for the complexity of the sedimentary substratum. We then compare the mechanical properties of dry and saturated, ‘as collected’ and heat-treated specimens as a function of applied stress and strain via conventional triaxial experiments. This combined suite of data allows us to expand the investigation and discussion of the strength evolution, on the role of water and thermal damage and to better constrain the deformation mechanisms related to the Brittle-Ductile Transition (BDT).

2. Background

Mount Etna volcano sits atop a structurally complex sedimentary basement. Etnean basement is dominated by formations consisting of sandstone, limestone, and clay that are part of the wider Appenninic-Maghrebian Chain (AMC). The AMC is part of the accretionary wedge of a regional fold-and-thrust belt that lies above the carbonate Hyblean Plateau (HP) sequences, which is part of the African plate (Fig. 1). The sedimentary covers of the HP present an average thickness of 6 km, and consist of mainly carbonate sequences (Mesozoic – Cenozoic) with volcanic intercalations: we selected carbonate samples from the Ragusa Formation (Branca et al. [2011]; Lentini et al. [2006]; black star, Fig 1) for our tests.

Geophysical models of the Mount Etna plumbing system suggest that an intermediate magma storage body exists at approximately 4-8 km b.s.l. (e.g. Bonaccorso et al. [2005], Aloisi et al. [2011]), which would place it partly within the sedimentary basement, rather than the dominantly basaltic edifice. This magma body affects the surrounding sedimentary rocks due to its elevated temperature, ranging from >1000 °C at the contact decreasing to 300 °C at a distance of about 1.5 km (Mollo et al. [2011]).
From a mechanical perspective, the effect of elevated temperature on carbonate rocks is known to be a function of several parameters including grain size, porosity, and strain rate (e.g. Rutter [1972]; Rutter [1974], Siegesmund S. [2000]). Recently, new data extended this knowledge to investigate the effect of high temperatures on triggering physical and chemical reactions via decarbonisation (e.g. Heap et al. [2013]; Mollo et al. [2011]; Bakker et al. [2015]). In one of these studies the physical and mechanical properties of two limestones (Climiti and Thala units (Heap et al. [2013]) were investigated in uniaxial and at in situ elevated temperature conditions. Both materials underwent decarbonisation reactions, with a total mass loss of 45 % occurring between 560-900°C, which accompanied a drastic change of the limestone physical properties. Increasing temperature and pressure resulted in a change in peak stresses in the brittle field, up to 500 °C, above which ductility was promoted (e.g. Bakker et al. [2015]), as the specimens started to ‘flow’ in an aseismic manner, with a strong dependence of flow stress on temperature (i.e. decreasing in dry elastic moduli, seismic velocities, and acoustic emission rate). It was suggested that such processes may be responsible for the large-scale deformation present at Mount Etna. This hypothesis is further reinforced by observations of clay dehydroxylation (Mollo et al. [2011]), along with a decreased strength which is likely to further promote flank instability and explain low seismicity zones, as well as the high local CO₂ overpressures. However, the limitation of these experiments is that they were conducted at ambient pressure conditions, rather than pressures which simulate burial depth. Nicolas et al. [2016] explored the brittle and semi-brittle behaviour of a 14.7 % porosity, ~100% calcite Tavel limestone and compared the results with CL in dry and saturated conditions, also using low in-situ temperature in an additional series of dry tests. Tavel limestone showed a brittle behaviour up to 55 MPa followed by a semi-brittle behaviour - defined by Evans et al. [1990] as a macroscopically distributed deformation involving micro-cracking and crystal plasticity - over 55 MPa. Water had a relatively small impact on the strength of Tavel limestone (Nicolas et al. [2016]). In addition, recent triaxial experiments performed on CL by Bakker et al. [2015] used representative shallow subsurface volcanic pressure conditions (specifically 50 and 100 MPa representative of 2 and 4 km depth).

Collectively, these studies support the hypothesis that both elevated temperature and pressure have significant effect on the mechanical strength of carbonate rocks. Confining pressure was found to limit the decarbonation reactions as a result of the decreased porosity due to increasing pressures, as well as the increased CO₂ fugacity, which has a major role in
controlling the decarbonation process (Mollo et al. [2011]). They identify that the brittle-ductile mechanical transition occurs at temperatures of approximately 350 °C, with 50 MPa confining pressure and constant strain rate at $10^{-5}$ s$^{-1}$. In addition to these investigations of induced damage at high temperatures, micro-crack damage is also inferred to occur during heating and cooling (e.g. Browning et al. [2016]). This latter effect is important as the injection of dykes and sills clearly expose the country rock to significant temperature gradients. Indeed, the increasing and decreasing amount of heat radiated by an intrusion into a body of country rock very likely play an important role on the rock’s temperature-dependent properties and processes, such as decarbonation in limestone, potentially further reflected in the overall deformation observed at the surface.

3. Material characterisation and methodology

3.1 Comiso Limestone and specimen preparation

Limestone samples were collected from the Ragusa Formation of the Western Hyblean Plateau, which occurs in monotonic layers that dip gently (335-16°) to the NNW. The Ragusa Formation is accessed in section via outcrops in a quarry near to Comiso village in SE Sicily (Fig.1a, black star). The Ragusa Formation has layers of maximum thickness of 60 cm, and is interlayered with unconsolidated clay-bearing strata. Carbonates from the Ragusa Formation are mainly composed of calcarenites (>50 % carbonate grains with a grain size ranging between 0.06 mm to 2 mm) and marls (carbonate-rich soft mudstone with grain size < 0.06 mm) of Lower Oligocene age (Lentini and Carbone [2014]). Carbonate within the formation are generally either a combination of calcite (CaCO$_3$) and dolomite (CaMg(CO$_3$)$_2$), or occasionally a pure calcite. A detailed description was provided by Bakker et al. [2015], who reported an initial, average porosity of 8.7 %, and density of 2.47 g/cm$^3$. The rocks used in this study have an average porosity of 10.1 % (measured with a helium pycnometer) and density of 2.47 g/cm$^3$. At the intralayer scale, the fabric is isotropic and CL is treated as an essentially homogeneous material. The CL used in this study is composed of calcite (97.7 %) and a small amount of quartz (2.3 % wt), as determined from X-Ray Diffraction and X-Ray Fluorescence analysis (see Figure S-1a in supporting material). All of the specimens used in this study were cored from the same sample using identical coring techniques to minimize specimen variation. In total, 14 cylindrical specimens (40 mm diameter (±0.03 mm) and with a length of 100mm (± 0.5 mm); Table 1) were cored from the CL sample using a diamond
coring drill, and a lathe fitted with a cross-cutting wheel to ensure parallelism to 0.01mm or better.

3.2 Thermal treatment

To investigate the effects of thermal stressing on CL properties, a suite of specimens were heated and allowed to cool prior to triaxial deformation tests. A selection of specimens were heat-treated using a high temperature, Carbolite CTF12/75/700 tube furnace (Browning et al. [2016]) between 150 °C and 600 °C to induce varying amounts of micro-fracture damage (Figure 2a). The specimens were held within a ~1 m length purpose-built steel jig comprised of rods and springs providing the specimen with a constant end load within the central section of the tube furnace. Temperature was controlled and monitored by a series of thermocouples mounted immediately adjacent to the specimen surface. In all tests, a controlled heating rate of 1°C/minute was applied, keeping the specimen at the desired maximum temperature for 30 minutes to allow complete temperature equilibration followed by natural cooling (generally less than <1°C/minute).

AE output was recorded contemporaneously during each test on heating to, and cooling from 150 °C, 300 °C, 450 °C, and 600 °C. AE were recorded by using the central rods to act as acoustic waveguides with one Panametrics V103 piezoelectric P-wave transducer located at the end of the waveguide. The AE hits are used as a proxy for the rate and relative amounts of induced crack damage which includes indistinctively he nucleation, coalescence and propagation of newly-formed microcracks (assumed to be the most likely source here) as well as well as other microstructural processes susceptible to produce AE (such as friction between pre-existing microcrack’s surfaces; Griffiths et al, 2018). A threshold of 35 dB was imposed on the recorded AE amplitude to avoid background noise (Browning et al. [2016]).

All thermal treatment tests were conducted at ambient pressure (1 atm). Complementary ultrasonic P-wave and S-wave velocity measurements were recorded on the starting material prior to heating, and on the cooled material following each thermal stressing test.

3.3 Triaxial deformation: method and data collection

The experiments were performed using a conventional triaxial apparatus (where \( \sigma_1 \) is the maximum principal stress, \( \sigma_2 \) the intermediate principal stress and \( \sigma_3 \) the minimum principal
stress such that $\sigma_1 > \sigma_2 = \sigma_3$; compressive stress is reckoned positive) capable of operating at a maximum confining pressure ($P_c = \sigma_2 = \sigma_3$) of up to 100 MPa, and an axial stress ($\sigma_1$) of up to 680 MPa across a 40 mm diameter cylindrical specimen (Figure 2b). An independent pore fluid system (using distilled water) was connected to the cell, which is capable of pressures up to 100 MPa via precision piston pumps (Fazio et al. [2017]). Dry conditions were achieved by leaving the specimens in an oven at approximately 85 °C for 12 hours to avoid the presence of interstitial water, followed by cooling in a desiccator for 1 hour. Saturated conditions were achieved by immersing a subset of the specimens in distilled water under vacuum for 24 hours. Axial displacement during tests was measured by three contactless transducers (external Foucault current sensors) positioned on the frame of the apparatus, averaged and logged by a control computer at 1 Hz. The same data logger recorded pore and confining pressures as well as pore volumes to allow specimen dilation to be derived. Axial stress data were corrected for the stiffness of the machine using a calibrated aluminium specimen of known Young’s modulus. We selected and applied a range of confining pressures ($P_c$: 7 MPa, 15 MPa, 30 MPa, and 54 MPa) simulating depths of 290 m, 620 m, 1.2 km, and 2.0 km respectively, assuming an average density of the overburden load of 2470 kg/m$^3$ (see Table 1).

Pore fluid pressures ($P_f$) were calculated accordingly to represent the same depths and assuming drained conditions: $P_f = 5$ MPa, 10 MPa, 20 MPa, and 34 MPa, respectively. To compare the dry and saturated data, we therefore maintain the same effective pressures applying a simple effective pressure law where the poroelastic constant $\alpha$ is assumed to be equal to unity ($P_{eff} = P_c - \alpha P_f$; Gueguen & Palciauskas [1994]). In that common frame, a dry test at $P_c = P_{eff} = 7$ MPa corresponds to a water saturated test where $P_c=12$ MPa, $P_f=5$ MPa and consequently $P_{eff} = 7$ MPa. To investigate and isolate the role of temperature treatment, $P_{eff} =15$ MPa was maintained in all tests using thermally-treated specimens.

All tests were conducted at $10^{-5}$ s$^{-1}$ axial strain rate in assumed drained conditions when relevant, and at room temperature. For saturated tests, the initial loading was applied in two steps, first by increasing $P_c$ hydrostatically ($\sigma_1=\sigma_2=\sigma_3$) until the desired confining pressure was reached, and then introducing pore fluid pressure, as per the functionality of our experimental set-up. We applied this method following Nicolas et al. [2016] who calculated the time of diffusion of water into a porous carbonate, concluding that for a quite significant porosity and standard axial strain rate (as used in our study) the specimens are fully saturated.
3.4 Ultrasonic surveys

In addition to mechanical and pore volume data, the deformation was monitored using an array of 12 piezoelectric lead zirconate titanate (PZT) sensors embedded in an engineered nitrile jacket (Sammonds [1999]). These sensors are sensitive to transient fracture events (micro seismicity) across a frequency range of approximately 80 kHz to 800 kHz. In addition to the standard passive AE recording, each sensor can be excited in sequence with a 200 V pulse, recording the travelling signal on the remaining 11 sensors to deduce the elastic P-wave velocity structure of the specimen during deformation: This is known as a velocity survey. Signals from each sensor are pre-amplified by a Pulser Amplifier Desktop (PAD) unit by 60 dB before being sent to an AE recorder (ITASCA-Image “Milne” unit). Active P-wave velocity surveys are processed using the known location of each sensor (3 sensors along a selected north direction, 3 sensors along south, 2 at north-west and 2 at south-west, for a total of 12; Figure 2c), and the signal travel time from the source to each receiver (e.g. Benson et al. [2007], Fazio et al. [2017]) determination of elastic anisotropy of the specimen during the application of differential stress. All ultrasonic data (passive AE and active velocity survey) are processed using the proprietary InSite-Lab software by cross-correlating a master pulse event with each received waveform, per survey, to achieve sub m/s (relative) accuracy.

4. Results

4.1 Thermal treatment: acoustic emission and ultrasonic wave velocities

Figure 3a shows the radial P-wave velocity ($V_p$) of each specimen as a function of the increasing thermal treatment. Concentric reduction in specimen radial-velocities shows that the carbonate remained isotropic even after the thermal treatment, and that overall velocity decreased with increasing maximum temperature. ‘As collected’ CL specimen has a radial P-wave velocity of 4.60 km/s (+/- 0.17 km/s) and are essentially isotropic (anisotropy < 4%). The change in P-wave velocity following the 150 °C thermal test is negligible and remains at approximately 4.60 km/s, overlapping the room-temperature specimen curve, therefore they are not reported here.

P-wave velocities decreased by approximately 5% to 4.26 km/s following heat treatment to 300 °C, and by 22 % to 3.55 km/s, following heat treatment to 450 °C. Following the 600 °C thermal stressing test, P-wave velocities decreased by approximately 37 % to 2.83 km/s (red line, Figure 3a). Figure 3b, c and d show AE outputs for tests heated to 300 °C, 450 °C and 600 °C. AE output was negligible in the 150 °C test and therefore is not reported. In tests
performed to maximum temperatures of 300 °C and 450 °C, the AE output is similar in terms of amplitude (size of individual AE hits) and number of AE hits. In both cases the total amount of AE hits is low (<1000 events). Tests with a maximum temperature of 600 °C show substantial AE output (Figure 3C). The rate and amplitude of AE hits increased substantially at approximately 480 minutes and 500 °C in heating and continued to produce AE at a similar rate and size on cooling. The total AE hits recorded in the 600 °C test exceeds 1000 events.

4.2 Triaxial test: dry conditions on ‘as collected’ specimens

Figure 4a shows the results from deformation experiments conducted on ‘as collected’ specimens of CL under dry conditions, at room temperature (22°C), with increasing levels of $P_{\text{eff}}$ (7 MPa, 15 MPa, 30 MPa, 50 MPa) representing increasing depth.

In the mechanical data we note a typical evolution from the brittle to the ductile regime as effective pressure increases beyond 30 MPa, with ductile behaviour clearly present at 50 MPa, defined as the capacity of the rock to undergo substantial strain without developing a microscopic fracture (Paterson and Wong [2005]) or loss of strength (Bakker et al, 2015). The two tests conducted at 50 MPa confining pressure exhibit small ‘bumps’ in the stress-strain curve. These represent steps of increasing confining pressure (each of 5 MPa). In all cases and across higher effective pressures, the specimens attained substantial strain without the development of a macroscopic shear fracture. All tests show an initial stage of strain hardening due to the closure of pre-existing cracks and/or pores (e.g. Baud et al 2000a; Nicolas et al, 2016) followed by linear elastic behaviour. Experiments 1, 2 and 7 (all dry) attained a peak stress at 116.23 MPa, 160.59 MPa and 184.41 MPa, respectively followed by strain softening and brittle failure (Fig. 4a and Table 1). To better understand the accommodation of deformation at the brittle to plastic (BP) transition, Figures 4b and 4c additionally plot the detail of experiment 7 (Dry, 30 MPa) and experiment 8 (Dry, 50 MPa).

Normalized $V_p$ and cumulative AE hit rates have been added to better understand the strain accommodation.

At $P_c = 30$ MPa (Fig. 4b), the $V_p$ velocities increase as well, up to 1.52% at 0.2% axial strain. Then, they start to decrease at the onset of inelastic deformation (0.4% axial strain), leading towards failure where the velocities reach a minimum. The most marked decreases in velocity are in the 3N-3S and 3E-3W directions, both at 90° respect to $\sigma_1$, corresponding to the directions travelling through the centre of the specimens. After failure velocity remains steady at between -8 to -35% below initial values; this directional variation in $V_p$ represents a
significant anisotropy. AE cumulative hit rate increased steadily during deformation and strain accommodation, showing a marked increase from the time of stress drop (dynamic failure), although only a small number of AE events were recorded.

At 50 MPa of $P_c$ (Fig. 4c), we observe a ductile behaviour, setting the BD transition somewhere between 30 and 50 MPa. The elastic-wave velocity data shows a path dependence with direction. An initial increase up to 1.55 % in the direction at 62° and 51° to $\sigma_1$ at 0.2 % axial strain, whereas there is no increase for the ray-path at 90°. For the first two ray-paths the velocity starts to decrease after the elastic accommodation reaches a value of -5 % and -10 %, respectively. The ray-path at 90° shows a continuous decreasing velocity to a minimum of -21.7 %. The $V_p$ velocities represent a lower anisotropy than tests at 30 MPa $P_c$. Cumulative AE data show a slow increase initially, which accelerates towards the end of the experiment.

4.3 Triaxial test: drained saturated conditions on ‘as collected’ specimens

Figure 4d presents data in drained saturated conditions. There are several notable differences in stress and strain accommodation compared to tests in dry conditions. Experiment 1 and 2 Sat attain a peak stress at 105.09 MPa, 0.76 % axial strain, and at 133.49 MPa, 1.01 % axial strain respectively followed by strain softening. The peak stresses are lower (between 5% and 20% MPa less) compared to dry conditions at equivalent effective pressure (cf. Fig. 4a and Table 1). Young’s modulus is also lower in saturated conditions (Table 1), and in general there is significantly more total strain accommodation before failure (such as the case of $P_{eff}=7$ and $P_{eff}=15$ MPa). At $P_{eff}=30$ MPa, the specimen accommodates strain hardening up to 1.5% axial strain, where a small stress drop is recorded. At 50 MPa the specimen is dominated by ductile deformation. The BD transition is again between 30 MPa and 50 MPa $P_{eff}$. AE are not reported for the experiments in Figures 4e and 4f, as the number of events were negligible.

The transition from brittle to ductile behaviour along with normalized $V_p$ are reported in Fig. 4e and Fig. 4f using data from experiment 7 Sat ($P_{eff}=34$ MPa) and experiment 8 Sat ($P_{eff}=54$ MPa) respectively. At $P_{eff}=30$ MPa the behaviour is characterized by strain hardening until brittle failure but the stress drop is barely discernible at around 1.5 % strain. Post-mortem macroscopic inspections revealed the presence of wedge splitting along with several conjugate fractures (see supporting material). The P-wave elastic velocity data remain
essentially constant throughout the experiment. The level of velocity anisotropy is low, with a range from -1 % to -5 % velocity decrease towards the end of the experiment.

At higher $P_{eff} = 50$ MPa (Fig. 4f), the divergence from elastic to plastic behaviour starts at 70 MPa differential stress or 0.3% strain, about 20 MPa less than the data reported in Fig. 5a. Similar trends are seen with regards to $V_p$ with in general a small continuously decreasing trend in the data for the velocities at 62° and 51° to $\sigma_1$ finally resulting in anisotropy values ranging between 0 % and -5 %. The ray-path travelling perpendicular to $\sigma_1$ is the most affected and decreases by 13%. The overall anisotropy is lower than the anisotropy recorded in the dry test (i.e. 8 Dry, fig 4c).

4.4 Triaxial tests: dry conditions on thermally treated specimens

Figure 5a shows mechanical results from triaxial experiments run at room temperature on previously thermally-treated CL. Here, a constant confining pressure was maintained at 15 MPa so as to investigate only the influence of the heat treatment, ranging from untreated (as collected) to 600 °C. All the specimens reached the same peak stress (160-162 MPa) before failure regardless of thermal treatment temperature with the exception of the specimen at 600 °C, which failed at 138 MPa peak stress. The stress-strain curves remain similar until treatment of approximately 450 °C. At 600 °C the behaviour starts to be weaker and in fact the Young's modulus is markedly lower compared to specimens treated at lower temperatures (see Table 1). The trend in total strain at failure is likewise tied to the thermal treatment temperature, with a tentative increase in the percentage strain at failure with increasing thermal treatment, but a clear behavioural variation is observed beyond 450 °C. Conversely, the stress drop itself appears to be constant (between 60 to 80 MPa) with the thermal treatments.

Figures 5b and 5c show detail of normalized $V_p$ and AE hit rates for the highest thermal treatment of 450 °C and 600 °C experiments. For experiment 5 Dry (450 °C), the initial strain accommodation is followed by elastic accommodation until approximately 80 MPa, 0.3 % axial strain. After the peak stress occurring at 0.9 %, the specimen enters a strain softening phase, with a complex strain softening behaviour. In comparison to the ‘as collected’ specimens where ultrasonic velocities show a small increment at the beginning of the experiments, here $V_p$ data shows an overall trend of higher velocities for the dry experiments.
prior to failure. For the 450 °C treated specimen, velocity data indicates a significant velocity anisotropy developing prior to failure, with velocities ranging from +8 % to -4 %. The most affected ray-path once again was at 90° to $\sigma_1$ which suggests the formation of axial fractures opening perpendicular to $\sigma_1$. For the specimen treated to 600 °C the behaviour appears similar. However, specimen strength is affected by the prior thermal treatment. In the specimen treated to 600 °C the peak stress occurred at 1.22 % axial strain and 134 MPa differential stress compared to the specimen treated at 450 °C where the peak stress occurred at 0.94 % axial strain and 164 MPa differential (Fig. 5c). In both cases the specimen developed a localized shear fracture. Also, in both cases, AE hit rate starts to increase dramatically when approaching the peak stress and failure, with a supra-exponential trend evident for the specimen treated to 600 °C, whilst the specimen treated to 450 °C has a more linear trend.

4.5 Triaxial tests: drained saturated conditions on thermally treated specimens

Figure 5d shows the stress versus strain results for thermally-treated specimens in saturated, drained conditions. Peak stress is lower across all specimens (about -30 MPa in all the experiments) compared to dry deformation (cfr. Fig. 4d and Table 1), and is very similar (approximately 132 MPa) to the lowest three thermal stressing temperatures (20 °C, 150 °C, 300 °C); stress-strain paths are virtually identical with a maximum strain at failure of approximately 1.4 %. Saturated conditions for the thermal treatment at 450 °C shows an increase in strain at failure to approximately 1.5 % and a slightly lower peak stress of 130 MPa. The presence of pore fluid pressure along with the thermal treatment at 600 °C resulted in a significant change in peak stress and stress-strain path, with strain at failure of 1.2 % and peak stress of 100 MPa. In all cases the strain accommodated before the peak stress and before failure is significantly increased relative to tests in dry conditions (Fig. 5a). Specimens show a systematic decrease in the static Young’s modulus with increasing thermal treatment temperature. Focusing on the transition from 450 °C (Figure 5e) to 600 °C (Figure 5f), in both experiments an initial increase in $V_p$ is recorded followed by a decrease, occurring at approximately 0.8 % strain for 450°C and approximately 1 % for 600 °C. As was the case for dry experiments, the normalised velocity increases initially with deformation from 0% to +7% in both cases, and ultimately giving anisotropy values ranging from -4 % to -16 % (450 °C) and +2 % to -10 % (600 °C). For experiment 5 Sat (450 °C) AE cumulative hit rate shows few events before yield and failure whereas the AE hit rate for experiment 6 Sat (600 °C)
°C) shows a significant AE hit count compared to the previous experiment from the beginning of the deformation, which increases discontinuously until the stress drop occurs.

5. Discussion

5.1 Mechanical behaviour of dry and saturated specimens ‘as collected’

For dry, ‘as collected’ specimens it is evident that a classical brittle to ductile behaviour starts to evolve when crossing a threshold confining pressure of approximately 30 MPa. The transition we observe is a steadily flattening and widening pre- and post-peak behaviour in the stress-strain curve. For dry experiments at 30 MPa, the amount of strain accommodated at peak stress is 1.26 %, considerably higher than that at 15 MPa (at 0.73 %). At 50 MPa the behaviour is in ductile regime. The experiment shows that strain hardening is generally insensitive to confining pressure increases (the jumps in the differential stress due to $P_c$ increase). Bakker et al. [2015] showed that for CL at 50 MPa confinement and $10^{-5}$ s$^{-1}$ strain rate, the specimen reached peak stress at 370 MPa of differential stress sustaining 1.8 % axial strain, with strain softening behaviour before failure. However, reviewing the specimen descriptions of Bakker et al. [2015] it is evident that their study used a more dolomitic material, compared with our calcite CL specimens. At the same confining pressure our specimens were already within the ductile regime. Nicolas et al. [2016] conducted dry experiments on Tavel Limestone, at the same constant axial strain rate and room temperature, which exhibited brittle behaviour for confining pressures up to 55 MPa. They found that for $P_c \geq 70$ MPa the behaviour changed to a semi-brittle regime, defined as a coupled plastic deformation and induced damage (Evans et al. [1990]). In our experiments the brittle-ductile transition is found to occur at confining pressures above 30 MPa, for specimens tested at room temperature and without thermal treatment. This is likely due to the larger grain size of CL compared to Tavel limestone (see Nicolas et al. [2016] and Vajdova et al. [2004]; Vajdova et al. [2010] for more details about Tavel limestone). As porosity and grain size increase, the brittle to cataclastic flow transition can occur at lower confinement (Wong and Baud [2012]).

In saturated conditions, Nicolas et al. [2016] the failure behaviour of the Tavel limestone in the brittle and semi-brittle regime. However, water did have a weakening effect lowering the peak stresses at which dilatancy occurred. In our water-saturated experiments, the response of CL changes at $P_{eff} < 30$ MPa. Water lowers the mechanical strength, decreasing peak stresses and promoting strain softening as seen for experiments 1 and 2 Sat (Figure 4d). Baud et al.
[2000] explained the reduction of sandstone brittle strength in presence of water integrating the Orowan's generalization of the Griffith-Irwin equilibrium concept (e.g. Lawn [1993]) in a sliding wing crack model. Since we recorded AE during the deformation of our saturated samples, we can assume that most of the brittle damage measured was controlled by micromechanisms at the grain-scale too. Water molecules could have lower the microcrack interface energy on entering and adsorbing onto the walls in the cohesion zones, diminishing the stress intensity in our saturated limestone samples compared to the dry ones. Experiment 7 Sat at $P_{\text{eff}} = 30$ MPa undergoes strain hardening until the deformation localizes, resulting in wedge splitting and conjugate fractures localized in the upper part of the sample. At $P_{\text{eff}} = 50$ MPa the behaviour of CL (experiment 8 Sat) is in the ductile regime, presenting strain hardening insensitive to increasing confining pressures (Figure 4f). As highlighted by previous studies, ultrasonic wave velocities and AE are both sensitive to inelastic damage, what can be crack nucleation and/or propagation under sufficiently high differential stresses ([Browning et al. [2017] and reference therein]). $V_p$ velocities are decreasing as crack damage is increasing. The behaviour of the recorded ultrasonic velocities for our experiments (Fig. 4b-c-e-f), is reflecting the previous findings. The $V_p$ velocities increase at the beginning of the tests when differential stress is applied, during closure of pre-existing micro-cracks ([Browning et al. [2017]]). The change in velocities at the onset of inelastic accommodation depends on the direction of the considered ray-paths. In general the most affected direction showing the higher anisotropy is the ray-path at 90° to $\sigma_1$, where travel is across newly-generated fractures. Encountering a high density of microcracks is increased with a high incidence angle, as consistently demonstrated in our data, and in common with other studies ([Harnett et al.], 2018).

5.2 Effects of thermal treatment on Comiso Limestone strength

In our experiments, pre-deformation thermal treatment is seen to have an influence on the rock mechanical properties. XRPD analyses on powders of specimens treated at 600 °C revealed the presence of Portlandite. As reported by Heap et al. [2013], Portlandite is a calcium hydroxide which is the result of the combination of CaO (product of decarbonation) with water in the atmosphere after the thermal treatment, according to the formula $\text{CaO}+\text{H}_2\text{O}=\text{Ca(OH)}_2$. As this is an exothermic reaction, it provokes an increase in volume, affecting the specimens even further (no measures of volumes are available here). Decarbonation has been reported to be one of the cause of weakening in strength ([Heap et al. [2013]; Mollo et al. [2011]]). A collection of SEM images of our thermally treated specimens

© 2018 American Geophysical Union. All rights reserved.
In our experiments, the pre-test thermal treatment illustrate an underlying thermal damage that is only partially characterised by AE output: at 150 °C CL does not show any significant AE output or damage, supported by unchanged P-wave velocities. Low AE counts in the 300 °C – 450 °C thermal stressing tests would also, apparently, indicate the absence of significant damage, however P-wave velocity decreases by up to 17 % over this temperature range (Fig 3 a,b,c), indicating indeed that thermal damage is present. We interpret that these temperatures do induce thermal damage but likely the low AE output is likely indicative of the natural variability of this rock. At 600 °C (Fig 3 a and d), the number of AE increase dramatically along with a consistent V_p decrease. At this temperature, different mechanisms of thermal damage might be activated, such as decarbonation and quartz α to quartz β transition (573 °C, ambient P: Tuttle, 1949) the latter corresponding to increasing volume. Elastic P-wave anisotropy measurements further confirm the development of a pervasive fracture damage that is extended and promoted by the thermal treatment. Regarding the results obtained
during the triaxial tests at room temperature, given the consistent nature of the peak strength of the thermally treated materials, it is thought that the previous heat treatment promoted inter-granular cracking (e.g. Fredrich and Wong [1986]) that locks the overall specimen to give a consistent strength, but with additional heating, allows a higher total strain at failure, as seen in the data (Figure 6). This influence extends in dry and saturated conditions, where the strength is at 160 MPa, between 0.57 % and 0.91 % axial strain and 130 MPa and 0.67 % to 1.22 % axial strain, respectively. Whilst the anisotropy reaches a maximum of 15 % (span ranging from -3 % to -18 %) for dry untreated specimens, this increase to 30 % (span +10 % to -20 %) after thermal treatment to 600 °C. The effect is subdued when water is present, increasing from 10 % (0 to -10) to 17 % (+7 to -10) due to thermal stressing, with the lower anisotropy providing further evidence of crack fabric, but this time filled with pore fluid that seeks to lower the effective elastic wave speed (e.g. Mavko et al. [1998]). The AE trend shows indeed an increment in the final output for the thermally treated specimens, whereas for the as collected specimens the trend is slightly flat and homogeneous throughout the experiments. Overall, with respect to the previous triaxial experiments run with in situ temperature, our previous thermal treatment assumes a different point of view. An in situ experiment aims to reproduce either a condition in depth or the presence of a magmatic body close to the rocks at the same time of the deformation. Triaxial tests at room temperature run on specimens previously treated and at modest confining pressures representing depth, aims to reproduce a common situation in volcanic environment: the intrusion of magma bodies which bring to the deterioration of the country rocks. Being deteriorated, these rocks will be more prone to fail and accommodate structural deformation which are of fundamental importance in the overall stability of the edifice.

5.3 Brittle-ductile transition

To provide a macroscopic description of the brittle-ductile transition, the data from all of our tests were plotted in strength vs $P_c$ space (Kohlstedt et al. [1995]) (Figure 6). For those experiments that produced ductile behaviour we measured the strength consistently at a threshold of 2 % axial strain. Byerlee’s Rule (black line) and the Goetze’s Criterion (dotted line) are reported as they delimit the brittle region from the semi-brittle region (Fig. 6).

We find that most of the experiments concentrate in the brittle region which is characterized by localized cataclastic flow. We highlight in Figure 6 the two end-member thermal treatment cases, RT (room temperature) and 600 °C both under dry and saturated conditions. The
specimen treated to 600 °C has a strength comparable to that of the saturated RT specimen indicating that both water and thermal cracking have a strong influence on strength. We also highlight the experiment under saturated conditions at $P_c=30$ MPa, which exhibited a strain hardening behaviour typical of the semi-brittle regime but which eventually reached failure (Figure 6). The two experiments that induced ductile behaviour fall in the transitional region, as confirmed from the macroscopic inspection of the post-mortem specimens. According to Evans and Kohlstedt [1995], these experiments transition to a failure mode from localized to ductile, into the mechanism class from brittle to semi-brittle, involving both plastic and brittle mechanisms. Our results explore only a single strain rate whilst the sensitivity of rock strength to strain rate is known to be very pronounced in the semi-brittle and ductile domain, especially in presence of continuous high temperature and/or creep conditions.

5.4 Application of results to the Etna basement

At Mount Etna previous studies have located the presence of shallow magma reservoirs between 3-5 km depth, within the sedimentary basement (Aloisi et al. [2011]; Bonaccorso et al. [1996], Bonaccorso et al. [2010]; Gambino et al. [2016]): this provides one of the key motivations for this study. Magmatic intrusions generate high temperature gradients, which can have a significant effect on the mechanical, chemical, and physical properties of the surrounding rocks, especially sedimentary rocks which are more prone to the effect of temperature and fluids circulation, promoting micro-cracking development and enhancing inelastic behaviour (Rutter [1972]; Rutter [1974]; Yavuz et al. [2010]; Mollo et al. [2011]; Heap et al. [2013]; Nicolas et al. [2016]). As carbonate rocks have a tendency to exhibit ductile behaviour already at laboratory temperature and strain rate (P. Baud et al. [2000]), the addition of fluids, and the thermal cracking effect, as shown here, will lead to ductile behaviour in the sedimentary basement. Magma reservoirs in the Etna’s sedimentary basement feed both central and lateral conduits as well as numerous dykes and sills (Aloisi et al. [2011], Bonaccorso et al. [2010], Gambino et al. [2016], Bonforte et al. [2008]). In general, dykes at Etna can be classified into two main types: a) horizontally propagating dykes that originated from a central conduit to the point of eruption (Sigmundsson et al. [2010]) and b) vertically propagating dykes fed from a shallow magma reservoir which bypass the central conduit and intrude through the entire basement towards the surface. This latter type is the more typical for the Etna’s basement (Aloisi et al. [2009]; Gambino et al. [2016]; Bonaccorso et al. [2010], Gudmundsson et al., [2002]). The volume of sedimentary substratum that is thermally affected by shallow magma reservoirs (3-5 km depth) at Mount
Etna is approximately 6 km$^3$, with a temperature gradient from 1200 °C to 300 °C at a radial distance of 1.5 km (Mollo et al. [2011] and reference therein). Magmatic intrusions, whether dykes or sills, or sub-spherical pressure sources, produce substantial heat which likely affects the basement rocks of Mt Etna, and other volcanoes with sedimentary substratum. To relate our laboratory data to a physical model considering the proximity to a dyke intrusion, we constructed a 2D finite element model using COMSOL Multiphysics (Figure 7).

Here, we consider the thermal effects on a carbonate host rock from the intrusion of a vertical basaltic dyke with a temperature of 1200 °C (Figure 7a). Using the heat transfer module in COMSOL, we build an axisymmetric 2D representation of a 1 m and 10 m thick dyke intruding into a cooler carbonate host rock with an average calcite thermal conductivity ($k_i$) of 2.5 W K$^{-1}$ m$^{-1}$, and a base temperature of 50 °C (Fig. 7a). A finite element mesh is created around the intrusion with a maximum resolution of 0.5 m. The model then solves the heat transfer equation (1) for conduction throughout the 20 km$^2$ domain to calculate the resultant temperature field of the host rock following intrusion (Fig. 7b) as follows:
\[ \rho C_p \cdot \Delta T + \Delta \cdot (-k \Delta T) = Q \]  

(1)

where \( \rho \) is density, \( C_p \) is specific heat capacity and \( Q \) is heating power per unit volume. This is a first order model that calculates the instant temperature field (\( \Delta T \)) in an isotropic dry host rock and so does not consider time dependant effects or preferred pathways for convective heat transfer or fluid rock interactions. The model therefore does not fully characterise the complexities of a thermal regime surrounding an intruded dyke but instead provides insights of the effect of temperature with proximity to a heat source. Applying this model to the heat-treated laboratory specimens suggests the expected approximate distance from the two different thicknesses of dykes that each specimen represents. In the case of a 1 m thick dyke intrusion, our four heat treated specimens represent a proximity to the dyke of 0.1 km at 600 °C, 0.2 km at 450 °C, 0.43 km at 300 °C, and 1.2 km at 150 °C. For a dyke of 10 m thickness, which is an extreme case for Etna, but commonly found at other volcanoes (e.g. Gudmundsson [1995]), the temperature field is much hotter which is entirely as expected. Increasing dyke thickness reduces the temperature decay at distance from the heat source: for a 10 m dyke, the 600 °C heat treatment would now be experienced at 0.3 km, 450 °C at 0.5 km, 300 °C at 0.95 km and 150 °C at 2.5 km from the dyke (Table 2).

Although being a quite simple model, when combined to laboratory analysis, one can observe that a dyke 1m thick can already exert a critical influence on the mechanical properties of CL present a few hundreds of metres away, and that this scenario may easily be extended across the depths where dykes and limestone are present in situ.

6. Conclusions

We have conducted a new series of experiments on Comiso limestone (CL) specimens. This study investigates the strength and strain accommodation dependence of the carbonate related to proximity to magmatic bodies and the presence of pore fluid, both as a function of burial depths (pressure) and fracture damage. Medium and high temperature were used to create thermal damage in the specimens prior to the mechanical testing to mimic the thermal stress of a distant heat source or the influence of a “recently cooled” magma body into the host carbonate rock. Based on our results, we conclude that even a modest temperature of 450 °C can affect the carbonate strength, which is relevant for the units present in the substratum underlying Mount Etna. At 600 °C does CL definitely become weaker, so below the decarbonisation point. Our triaxial experiments confirmed that CL does not generate significant acoustic emissions, at least up to 450 °C of thermal treatment. However, a
substantial development of new micro-cracks between 300 °C to 450 °C has been detected by the recording of ultrasonic wave velocities after the thermal treatment, which decreased from 4.26 km/s to 3.55 km/s and up to 2.83 km/s at 600 °C. Additionally, our study highlights that the marked decrease in mechanical strength of CL either due to thermal damage or the presence of water (pore fluid) enhances inelastic strain accommodation without dynamic failure by promoting the brittle-ductile transition regime of deformation at shallower depths. Finally, even if beyond the primary scope of our study, our modelling results indicate that the critical aseismic temperature zone in relation to the CL unit is likely to extend as far away as 2.5 km away from a 10 m thick dyke, a distance encompassing a large thickness of sub-Etna pile if applicable, thus suggesting a very ductile substratum. In any case, our study presses the need to better assess the deformation of volcanic basements, with wide applications to other tectonic settings (as for instance the Campi Flegrei, Italy) and geothermal and reservoir fields.

Acknowledgements

Figure 1. Top panel: Illustration of the main structural features and lithological units in and around Sicily (Italy): dark grey for the Kabilo-Calabride Chain, medium grey for the Appenninic-Maghrebian Chain, light grey for the Hyblean Plateau units, and very light grey for the volcanic units of Mount Etna. The black star locates the CL quarry. Lower panel shows a cross-section along line A-B in the top panel across Mount Etna, highlighting the key stratigraphic and structural relationships in the sedimentary basement of Mount Etna. All modified and simplified after Branca et al, 2011.
Figure 2. Schematic views of: a) the Carbolite furnace used to thermally treat specimens. The specimens is held within the centre of the tube furnace, where the temperature remains constant. The two springs at the end of the jig allow contraction and expansion, registered by a transducer used for AE recording; b) the triaxial apparatus used; and c) the AE sensor positions and orientations around a half-specimen (originally 40mm in diameter and 100 mm in length) in the arbitrary orientation system. The degrees are reported with respect to the maximum principal stress applied $\sigma_1$ (i.e. in the vertical direction here).
Figure 3. a) Radial ultrasonic P-wave velocities (km/s) as measured across the diameter of a cylindrical specimen at 15° increments. The thick black line represents the untreated (i.e., as-collected) specimen, reporting a P-wave velocity of 4.60 km/s. Lines represent the P-wave velocities as measured with increasing thermal temperature treatment. (b), (c) and (d) represent the contemporaneous acoustic emission output recorded during the thermal treatment at 300 °C, 450 °C and 600 °C respectively. Note the change of scale in cumulative AE hits in part d.
Figure 4 (a-c). Triaxial test results in dry conditions, for non-thermally-treated specimens. (a) Differential stress versus axial strain, as a function of increasing confining pressure (see inset key). (b) and (c) are stress-strain plots with corresponding, normalized, ultrasonic velocities along three representative directions, and cumulative AE hit count (red line) for the test conducted at (b) 30 MPa and (c) 50 MPa effective pressure.

Figure 4 (d-e-f) are the triaxial test results in drained, saturated conditions, for non-thermally-treated specimens. AE hit count it is not reported as the event rate was too low. In the final tests (Figure 4c and f), Pc was increased in steps of 5 MPa after 1% and 2.2% strain, respectively, in attempt to check for changing behaviour in the ductile response as a function of burial depth, using the same experimental setup. The increasing Pc steps result in small differential stress ‘bumps’ in the stress-strain curves.
Figure 5 (a-b-c). Triaxial test results in dry conditions for thermally-treated specimens, at a constant 15 MPa effective pressure. (a) Differential stress versus axial strain, as a function of maximum thermal treatment temperature (see inset key). (b and c) Stress-strain plots with corresponding, normalized, ultrasonic velocities along three representative directions, and cumulative AE hit count (red line) for the test conducted on specimens treated to (b) 450°C and (c) 600°C. Note the initial increase in ultrasonic velocities in c) across all raypaths likely indicating thermal induced micro-cracking, followed by velocities reduction corresponding to an increase in AE hit count. Figure 5 (d-e-f) are the triaxial test results in drained, saturated conditions for thermally-treated specimens, at a constant 15 MPa effective pressure.
Figure 6: Experimental results plotted on a strength vs $P_c$ plot.
Figure 7. 2D finite element model representing a dyke as heat source (of 1200°C) embedded in a cooler carbonate host rock (of 50 °C). (A). Model set-up and parameters. (B) Model results showing temperature decay away from a 1 m thick dyke. (C) Temperature versus distance plot for a 1 m thick dyke, and for a 10 m thick dyke. Inset shows zoomed view up to 600°C, for a distance up to 3 km. Thin dashed lines show representative temperatures as per the thermal treatment experiments. Data are summarised in Table 2.
