INTRODUCTION

The desire to mimic the optical properties of natural teeth with ceramic systems has always been a major challenge for modern dentistry.\textsuperscript{1} For PFM restorations, the presence of a metallic substructure, which is a total barrier to the transmission of light, creates unfavorable chromatic properties due to the increased light reflectivity.\textsuperscript{2,3} Many all-ceramic systems have been developed over the past forty years to overcome the esthetic deficiencies of PFM,\textsuperscript{4} and more recently CAD/CAM technology has facilitated the use of newer materials.

The translucency of metal-free materials is an important esthetic advantage but adds a higher level of complexity to the shade matching process,\textsuperscript{6} and the limited color availability of machinable CAD/CAM blocks or disks is an important limitation in the color matching process.

The final color of all-ceramic restorations is not merely a shade selection process, but rather the combined result of several factors, including the degree of translucency, the thickness of the restoration, the surface characteristics such as gloss and roughness, the color and the opacity of the luting agents.\textsuperscript{7}

It is well documented that white opaque cements are indicated with stained or metallic abutments, to mask the color of the substrates.\textsuperscript{8} Furthermore, it is well known that the shade of a feldspathic ceramic restoration is more readily influenced than that of a zirconia restoration, due to the different translucency of the ceramic structure.\textsuperscript{9} Similarly, the color after cementation of thin veneers can be more easily influenced by the color of the resin cement, compared with thicker crowns made with the same material, where the effect of the color of the cement is lower.\textsuperscript{10} Recently the influence of cement has been reported as one of the factors able to influence the shade of zirconia based restoration due to their increased translucency.\textsuperscript{11,12} Although the observation that translucency is influenced by the wall thickness has been reported for feldspathic ceramic\textsuperscript{13,14}, and recently for lithium disilicate\textsuperscript{15,16} and zirconia\textsuperscript{17}, limited clinical guides are available\textsuperscript{18} and no studies correlating color and opacity of cement and ceramic are present in the literature.
For this reason, the influence of color and opacity of luting cements on the final shade of ceramic restorations of different thickness, and consequently variable translucency, was investigated in this study.

The formulated null-hypotheses were:
i: After the cementation procedure, the color of resin cement does not influence the final shade of different thicknesses of feldspatic restorations.

ii: No linear correlation exists between the influence of cement and the optical properties (color and translucency) of cement and ceramic.
MATERIALS AND METHODS

Five resin cement colors were tested in combination with four different translucencies of CAD/CAM feldspathic ceramic, using different specimen thicknesses, on a composite substrate used as a dentin color reference, for a total of 20 combinations (n=3).

Sixty disks (15 mm diameter x 2 mm thickness) of Herculite XRV Ultra Dentine #A2 (Kerr Italia s.r.l., Scafati SA, Italy; #34019) were used as substrates. A calibrated mold was employed to control the diameter and thickness of the disks. A glass plate was pressed on the mold to eliminate the excess of material and then polymerization was performed by a halogen lamp (VIP Bisco, Schaumburg, IL, USA). Composite disks were removed from the mold, finished and polished in a grinder/polisher machine (EXTEC® Labpol 8, Extec Corp. Enfield, CT, USA) with #600, #1000 and #1200 silica-carbide paper (South Bay Technology, Inc., San Clemente, CA, USA).

VITA Mark II #2M2 (Vita Zahnfabrik, Bad Sackingen, Germany; #19050) CAD/CAM ceramic blocks were perpendicularly cut with a water-cooled low speed diamond saw (Isomet, Buehler, Lake Bluff, IL, USA). Flat 14 mm x 12 mm specimens of variable thicknesses of 0.5, 1.0, 1.5 and 2.0 mm, were cut. A special support maintained the block insertion pin perpendicular to the saw during cutting, to ensure a consistent thickness of specimen. To simulate clinical conditions, in which the external surface of the restoration is finished and polished while the intaglio surface is treated for cementation, one side of the specimens was glazed with VITA Akzent Glaze Spray (Vita Zahnfabrik, Bad Sackingen, Germany) and fired in a VITA Vacumat 4000T (Vita Zahnfabrik, Bad Sackingen, Germany), following the manufacturer’s instructions.

The color evaluations were performed with a spectrophotometer (OceanOptics PSD1000) equipped with a 10.0 mm opening integrating sphere (OceanOptics ISP-REF). The spectrophotometer was connected to a computer running color measurement software (OOILab 1.0, Ocean Optics, FL, USA). D65 illumination and a 10° standard observation angle were selected. Measurements were taken using the CIELAB color coordinate system against a neutral gray background (Kodak, Rochester NY, USA). The output of the spectrophotometer was set over 10 scans.
To identify the color differences before and after cementation, the initial color of the complex ceramic and composite substrate was assessed before cementation. Glycerin was used instead of cement to avoid light scattering during color measurement. After initial measurement, the specimens were cleared of the glycerin in an ultrasonic bath and then submitted to the cementation procedure. The glaze free surface was submitted to the etching procedure with 4.9% hydrofluoric acid (VITA ceramics etch, Vita Zahnfabrik, Bad Sackingen, Germany) for 20 seconds.

The clear, white, yellow, brown and white opaque shades of the self-adhesive resin cement Maxcem Elite™ (Kerr Italia s.r.l., Scafati SA, Italy; #34062) were selected.

To simulate the clinical bonding procedure and ensure a constant cement thickness, a 100 µm spacer was placed on top of the substrate disk (Figure 1) and a standardized seating force of 40 g/mm² was applied over the ceramic specimen and the composite substrate disk. The application of this seating pressure on a 15mm diameter composite disk is equivalent to a force of about 70 N, which can be considered a medium seating force and a moderate biting force. The specimens were maintained under pressure for 10 minutes, allowing the cement to self-cure. Three specimens were prepared for each cement color and each ceramic thickness combination.

Spectrophotometric color measurements were performed with the same setup previously described. To calculate the differences in color before and after cementation (ΔEi), the CIEDE2000 formula was applied.

\[
\Delta E_{00} = \sqrt{\left(\frac{\Delta L'}{K_L S_L}\right)^2 + \left(\frac{\Delta C'}{K_C S_C}\right)^2 + \left(\frac{\Delta H'}{K_H S_H}\right)^2 + R_T \left(\frac{\Delta C'}{K_C S_C}\right) \left(\frac{\Delta H'}{K_H S_H}\right)}
\]

where \(\Delta L', \Delta C',\) and \(\Delta H'\) are the differences in lightness, chroma, and hue for a pair of samples in CIEDE2000, and \(R_T\) is a function that accounts for the interaction between chroma and hue differences in the blue region. Weighting functions, \(S_L, S_C, S_H\) adjust the total color difference for variation in the location of the color difference pair in \(L', a', b'\) coordinates and the parametric factors, \(K_L, K_C, K_H,\) are correction terms for experimental conditions. In the present study, the parametric factors of the CIEDE2000 color difference formula were set to 1.24-26
For the cement and ceramic color and opacity assessments 1.0±0.1 mm thick disk specimens were produced for each of the cement shades in the same way as described before for the composite substrate. One extra 1 mm thick ceramic specimen was prepared for color evaluation. Spectrophotometric color evaluation was performed against a 50% gray standard background. CIELAB values were recorded, and the color coordinates were assessed over 10 scans. The differences in color between the ceramic specimens and the cement disks ($\Delta E_{cc}$) were calculated applying the CIEDE2000 formula to evaluate the magnitude of the color differences and to correlate them with the influence of the cement on ceramic color, after cementation ($\Delta E_{fi}$).

The relative translucency of the five cement colors (1mm thick disks) and the ceramic specimens for all the tested thicknesses, were analyzed by measuring the translucency parameter (TP). The TP was calculated using the following CIELAB color difference equation:

$$TP_{ab} = \sqrt{\left(\Delta L^*_{b} - \Delta L^*_{w}\right)^2 + \left(\Delta a^*_{b} - \Delta a^*_{w}\right)^2 + \left(\Delta b^*_{b} - \Delta b^*_{w}\right)^2}$$

where the subscripts “b” and “w” refer to color coordinates over black (CIELAB 0,0,0 – 3% reflectivity) and white (CIELAB 100,0,0 – 90% reflectivity) backgrounds (Kodak Gray Scale Q-14, Rochester NY, USA).

Calculated data were reported in Table 1. The differences in translucency between the 4 tested ceramic thicknesses and the cement specimens, were calculated using the formula $\Delta TP = TP_{cer} - TP_{cem}$. The mean $\Delta TP$ was calculated for each ceramic thickness and was compared to the $\Delta E_{fi}$ to evaluate the role of both ceramic and cement translucency, on the color of the restoration after cementation.

The $\Delta E_{fi}$ values were statistically analyzed for the variables Cement Shade and Ceramic Thickness by applying the Two-Way ANOVA followed by the Tukey Test for post-hoc comparison (p<0.05). The acceptability (AT) and perceptibility (PT) thresholds were set respectively at $\Delta E_{00}$ 1.8 and 0.825.26 and the color mismatch was classified as indicated by Paravina et al.27

Multiple correlation analyses between $\Delta E_{cc}$ and $\Delta E_{fi}$ were performed, pooled data were divided into groups based on the 4 levels of mean $\Delta TP$ between the tested cements and their specific ceramic thickness (Group 1 to 4 respectively -10.45, -6.34, -2.86 and 7.15 $\Delta TP$).
The whole data were again divided into 5 groups based on the level of $\Delta E_{cc}$ (Group 1 to 5 respectively 6.53, 10.16, 10.20, 11.03 and 15.31 $\Delta E_{cc}$) for the correlation between $\Delta TP$ and $\Delta Ef$. The level of linear correlation was determined by evaluating Pearson’s correlation values “$r^2$”.
RESULTS

The mean values for $\Delta E_f$, the statistical significance for the variables Cement color and Ceramic thickness and the classification in terms of color differences were reported in Table 2.

A statistically significant influence on final color was found between 0.5 mm, 1.0 mm and 1.5 mm thick specimens. No significant differences were found between the 1.5 mm and 2.0 mm thicknesses.

The white opaque cement showed the greatest influence on color compared to all the other tested shades of resin cements. A significant influence was reported also for the Brown shade while no statistically significant influence was found for the clear, white and yellow cement colors.

The 0.5 mm thick ceramic specimens were influenced for all the cement colors with respect to the AT threshold. Varying color changes were observed within the tested combinations.

The data expressing the strength of the correlation between the influence of cement on cementation and factors influencing the shade are summarized in Table 3. Considering the influence of the difference in color between the ceramic and the cement ($\Delta E_f$ Vs. $\Delta E_{cc}$, Figure 2), a strong linear correlation was found only with a positive $\Delta TP$ ($\Delta TP=7.15$). Evaluation of the influence of the different translucencies between cement and ceramic and the influence of the final shade after cementation ($\Delta E_f$ Vs. $\Delta TP$, Figure 3), demonstrated a strong linear correlation ($r^2 > 0.6$) only when the $\Delta E_{cc}$ was greater than 11.
DISCUSSION

The results revealed differences in the color of the specimen after cementation.

Since the differences were statistically significant, the first null-hypothesis was rejected.

The correlation analysis showed strong correlations for positive ΔTP and ΔEcc greater than 11, therefore the second null-hypothesis was partially rejected.

The wide range of translucencies and colors that can be achieved with the materials tested in the present study, were measured to quantify factors that are usually described as categorical variables. Hence, statistical analysis allowed a more scientific description to be applied to the influence of the resin cement on the final color of metal-free restorations.

Based on the results of the present study, no significant color changes were introduced into the final restoration by the cement when its color was close to that of the restoration and the translucency was higher than the restoration. Conversely, when the opacity of the cement was higher than that of the restoration, significant color changes were measured. Contrary to the current manufacturer held view that several marketed resin cement shades are required, it is reasonable to observe that a variety of shaded very translucent cements could be unnecessary for the majority of the delivered ceramic restorations. Opaque and shaded cements, not only in the white shade, could be helpful for the clinician in certain situations, such as where dichromic abutments are used or when minor color corrections are required.

The translucency of metal-free restorations significantly improved their esthetics. A wide range of translucencies was reported for ceramic materials and this is a pivotal factor for luting procedures and thereby for the optical performance of the final restoration, for both translucency and color.

Chang et al. found that the color of the cement substrate could influence the final color of the CAD/CAM lithium disilicate crown. Similar conclusions were drawn by Turgut & Bagis for heat pressed lithium disilicate veneers. Alghazzawi et al. reported how in a spectrophotometric analysis
of feldspathic, lithium disilicate and zirconia veneers, the influence of the cement was present for feldspathic and lithium disilicate and absent for the zirconia veneers, due to their intrinsic opacity.

In an *in vitro* test on Leucite-reinforced glass ceramic, Karaagacioglu & Yilmaz\(^37\) reported the influence of the cement color when the thickness of the veneers was less than 0.8 mm. For most of the published papers, the analyzed variables were: i) the ceramic thickness,\(^10,38-41\) ii) the ceramic structure \(^9,42,43\) and iii) the cement shade.\(^44-46\)

An evident problem of this area of interest is that the cement shade is usually named after the generic hue (e.g. White, Yellow, Brown) or is based on the VITA classical shade guide. For some brands, a translucency index was added (e.g. HT, LT, Opaque). This classification has been criticized as differences were reported between the same shades of different cement brands.\(^47\) Thus, shade definitions can be considered material-dependent and not universal. This resulted in material dependent results because similar nominal shades like (e.g. clear or yellow) could have a different influence on the final restoration, thereby not addressing the goal of esthetic indirect restorations in terms of color matching.

The same criticism could be used when thickness and ceramic structure were indicated as categorical variables. Ceramic translucency is influenced by the thickness and by the structure of the ceramic and plays an important role on influencing the final color of metal-free restorations.\(^48\)

The presence of an opaque layer of cement beneath a translucent ceramic restoration is usually described in the literature as having the function of masking a discolored abutment or titanium implant abutment and its influence on the final color of metal-free restorations is limited.\(^8,49-51\) This opaque layer of cement can influence the light transmitted through the restoration, reflecting most of its spectral composition. In the present study only a tooth colored background was applied in combination the only opaque cement color available. This limitation of the study suggests the needing of further investigations to confirm the possible deduction derived from the correlation analysis.

By the use of shaded opaque resin cements, clinicians can correct the appearance of all types of cemented ceramic restorations, by using a cement opaquer. This is a difficult aspect in clinical
situations where the exact translucency of every single part of the restoration can not be measured. However, from the results of the present in vitro study, in order to influence the final color of a restoration, a cement opaquer is needed. Therefore, in order to correctly influence the final color of the restoration, a more extensive range of opaque resin cements colors should be available. This will require further investigation, in order to provide clinicians with more detailed information, relating to any color modification of the final metal-free restoration. The unavailability of a greater variety of shades and opacities of the resin cement was the main limiting factor for this in vitro study. Likewise, in vivo clinical studies using try-in pastes and a clinical spectrophotometer, would be helpful to support the in vitro the results of this study.
CONCLUSION

Based on the results and within the limitations of the present study, it can be concluded that:

- The final shade of ceramic restorations can be significantly influenced using resin cements, by virtue of their cement optical properties.

- The final shade of a ceramic restoration is highly influenced by the translucency and the color of the complex ceramic cement. Translucent resin cements showed a low influence on the color of the final restoration and their different shades seem to be ineffective and unnecessary. Conversely, shaded resin cement opaquer could be useful to influence the color of the restoration in cases where there is a color mismatch within the desired shade.
